
Topic: Nonlinear restrictions, dummy variables, and nonlinear least squares

---

- This problem set covers three distinct topics: testing nonlinear hypotheses on parameters estimated from a linear model, inclusion and interpretation of dummy variables within a regression model, and nonlinear least squares (NLS) estimation.
- We use data on annual U.S. aggregate income (Y_t) and consumption (C_t) over the period 1950 – 1985 ($t = 1, 2, \ldots, T = 36$), available as `income_consumption.txt` on the website. Import the data into a **dated** workfile as `year`, `inc` and `cons`.
- Refer to Figures 1 – 4, and answer the following questions:[1]

1. Perform a brief descriptive analysis of the dataset. Consider the rates of change of C_t and Y_t over time. Then estimate the following dynamic consumption function (this is an example of a 'distributed lag model', in which lagged values of the dependent variable appear as explanatory variables):

$$C_t = \alpha + \beta Y_t + \gamma C_{t-1} + u_t.$$

Carefully interpret the regression output. The estimated short-run marginal propensity to consume (SRMPC) is defined as:

$$\widehat{\text{SRMPC}} = \widehat{\frac{\partial C_t}{\partial Y_t}} = \widehat{\beta}.$$

[1] Note that not all of the necessary steps are shown in the figures.

Now imagine that the dynamic system has settled into an equilibrium given the estimated parameters: $C_t = C_{t-1} := C^\star$ and $Y_t = Y_{t-1} := Y^\star$ and $u_t = u_{t-1} = 0$ (where $C^\star$ and $Y^\star$ are respectively the 'long-run' values of consumption and income). The estimated long-run marginal propensity to consume (LRMPC) is then defined as:

$$\widehat{\text{LRMPC}} = \widehat{\frac{\partial C^\star}{\partial Y^\star}} = \frac{\widehat{\beta}}{1-\widehat{\gamma}} := \widehat{\delta}.$$

Check that you can derive this. Then test whether the LRMPC is equal to 1, against the two-sided alternative, using both a linear hypothesis:

$$H_0 : \delta = 1 \quad \Longrightarrow \quad H_0 : \beta = 1 - \gamma.$$

and a **nonlinear hypothesis**:

$$H_0 : \delta = 1 \quad \Longrightarrow \quad H_0 : \frac{\beta}{1-\gamma} = 1,$$

What do you notice about the results?[2]

2. Was there a structural break in income growth between 1962 and 1963? (i.e., is the mean growth rate from 1963 onwards different to the mean growth rate up until 1962?) Hint: estimate the following model:

$$Y_t = (\alpha + \beta D_{\texttt{year}_t \geq 1963}) + (\gamma + \lambda D_{\texttt{year}_t \geq 1963})\texttt{year}_t + u_t,$$

where $D_{\mathcal{A}}$ is a **dummy variable** that takes value 1 when condition $\mathcal{A}$ is satisfied, and 0 otherwise. Think carefully about the null hypothesis. Hint: consider the implication of each of $(\beta = 0, \lambda = 0)$, $(\beta \neq 0, \lambda = 0)$, $(\beta = 0, \lambda \neq 0)$ and

[2] We do not assume any knowledge of the difficulties that can arise in modelling (these) time series.

($\beta \neq 0, \lambda \neq 0$). Perform and interpret any relevant tests, and plot the fitted model. Can you suggest any limitations of using dummy variables to test for structural breaks in this way?

3. Estimate the nonlinear regression:

$$C_t = \alpha + \beta Y_t^{\gamma} + u_t, \tag{1}$$

with parameters $\theta = (\alpha, \beta, \gamma)'$, using **nonlinear least squares** (NLS) $\widehat{\theta}_N = \arg\min_{\theta} u'u$. This is a numerical procedure, since in general $\widehat{\theta}_N$ will not have a closed-form solution. It can be difficult to find starting values $\theta^{\dagger}$ for the parameters in a numerical optimization. There is no good rule, but here we can use the linear model, which is a special case of (1):

$$C_t = \alpha + \beta Y_t + u_t, \tag{2}$$

to provide 'natural' starting values. Run the linear regression (2) first, and then set the parameters $\alpha^{\dagger}$ and $\beta^{\dagger}$ equal to the OLS estimates. You can set $\gamma^{\dagger} = 1$. Then estimate (1).

Test the null hypothesis $H_0 : \gamma = 1$ in (1), at the 95% level of significance. Then test whether the SRMPC is (a) constant (but not necessarily equal to 0), and (b) equal to 1, at the 95% level of significance. Explain your results.

Figure 3: Ordinary least squares regression of income on a constant and year, and interactions with a dummy variable $D_{\texttt{year}_t \geq 1963}$. Plot of the fitted model and residuals, and observed income, against year.

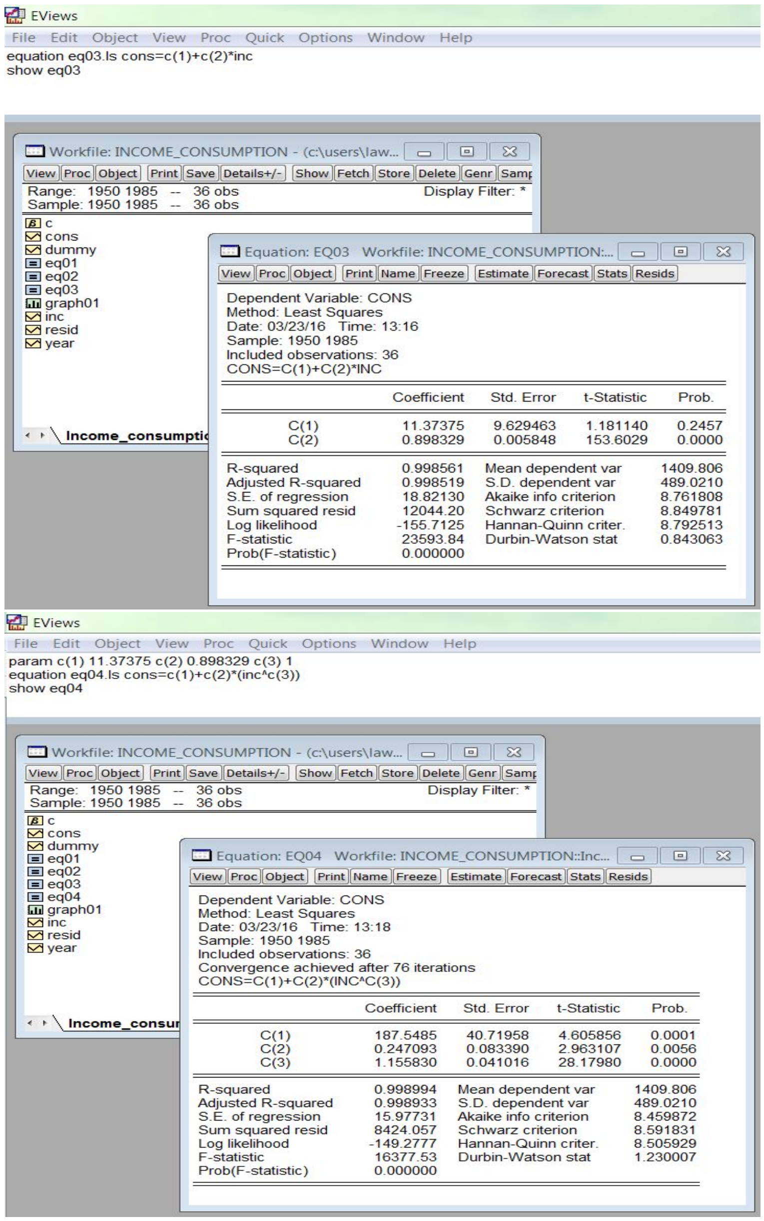

Figure 4: Ordinary least squares regression of consumption on a constant and income. Use the starting values $\alpha^\dagger = 11.37375$ and $\beta^\dagger = 0.898329$ and $\gamma^\dagger = 1$ to find the *nonlinear* least squares estimates $\widehat{\theta}_N = (\widehat{\alpha}_N, \widehat{\beta}_N, \widehat{\gamma}_N)'$ from a model of consumption on a constant and a coefficient multiplied by income raised to a power. Note that we must specify the coefficients explicitly in a nonlinear model.
